THE EFFECT OF INCREASE IN COMBUSTION-AIR INLET TEMPERATURE FROM 80° TO 130° F ON THE SEA-LEVEL PERFORMANCE OF A 22 INCH-DIAMETER PULSE-JET ENGINE

By Michael F. Valerino, Robert H. Essig
and Richard F. Hughes

SUMMARY

Data from a sea-level investigation of a 22-inch-diameter pulse-jet engine installed on a thrust stand were analyzed to determine the effect on the engine performance of a change in combustion-air temperature from approximately 80° to 130° F. The tests at both combustion-air temperatures covered a range of simulated ram pressures from 19 to 58 inches of water for the fuel-flow range of resonant operation.

The results show that, when the combustion-air temperature was increased from 80° to 130° F for the same conditions of fuel flow and simulated ram pressure, the jet thrust was reduced about 6 to 10 percent, which is roughly equivalent to the percentage increase in absolute temperature of the combustion air. This reduction in jet thrust was accompanied by a reduction of only 0 to 4 percent in combustion-air flow thus indicating that the loss in engine performance with increase in combustion-air temperature is due to reduced engine thermal efficiency as well as decreased combustion-air consumption.

INTRODUCTION

At the request of the Air Materiel Command, Army Air Forces, and the Bureau of Aeronautics, Navy Department, an investigation is being conducted at the NACA Cleveland laboratory to improve the performance and to extend the operating life of the pulse-jet engine. As part of this investigation, thrust-stand tests were conducted to determine the sea-level performance of a 22-inch-diameter pulse-jet engine at simulated ram pressures of approximately 0, 18, 40, and 58 inches of water over the entire fuel-flow range of resonant operation (reference 1). The temperature of the combustion air in these tests was of the order of 80° F.

In addition to the tests of reference 1, endurance tests were conducted on the 22-inch-diameter pulse-jet engine equipped with a standard flapper-valve grid assembly that was modified by the use of a shock-absorbing neoprene coating over the grid surfaces (reference 2). Part of the endurance tests were conducted at comparable operating conditions with combustion-air temperatures of 80° and 130° F.

The test data obtained in reference 2 at combustion-air temperatures of approximately 80° and 130° F are analyzed herein to determine the effect of combustion-air temperature on the performance of the pulse-jet engine. In order to provide a further check on the effect of the combustion-air temperature, limited tests were conducted with a standard grid assembly at a combustion-air temperature of approximately 130° F and the test results are compared with those of reference 1.

APPARATUS AND METHODS

The data analyzed herein were obtained from tests of the 22-inch-diameter pulse-jet engine using both a standard grid assembly and a neoprene-coated grid assembly. The neoprene-coated grid assembly was made by coating the entire grid surfaces of a standard grid assembly with a thin layer of neoprene (reference 2). The principal dimensions of the engine shell and the positions of the flapper-valve grid assembly and venturi are shown in figure 1. The thrust stand, the method of simulating ram pressure, and other installation and instrumentation details are essentially the same as described in reference 1.

During the tests, the combustion-air temperature was varied and controlled by means of an air-tempering tank located in the combustion-air ducting system (reference 1). The air-tempering tank contained separate steam and water coils and automatically controlled louvers for regulating the relative flow of combustion air through the hot and cold portions of the tank. The lowest and highest temperatures obtainable in the tests were about 80° and 130° F, respectively. The nature of the temperature-control equipment did not permit precise regulation of the combustion-air temperature during the tests.

The range of simulated ram pressure, fuel flow, and combustion-air temperature covered is presented in the following table:

Grid assembly	Nominal simulated ram pressure (in. water)	Fuel-flow range (lb/hr)	Nominal combustion-air temperature (°F)	Source of test data
Neoprene-coated	19 38 58	2000-2400 2200-3000 2400-3400	80, 130 80, 130 80, 130	Reference 2
Standard	38 57	2000-3000 2400-3200	130 130	Subject Report
	40 58	2000-3000 2200-3400	80 80	Reference 1

The procedure followed in setting and obtaining stabilization of the test conditions and in recording the test data is described in reference 1.

In the tests with the neoprene-coated grid assembly, comparable operating conditions for the two values of combustion-air temperature were within 3 minutes of engine operation. This procedure assures that the measured effects of combustion-air temperature on engine performance do not include any effects of possible valve deterioration obtained during the tests.

The tests with the standard grid assembly were conducted at a combustion-air temperature of approximately 130° F in order to afford a comparison with the results of reference 1 obtained at a combustion-air temperature of 80° F. Because of the limited number of points obtained at 130° F, the performance comparison at the two values of combustion-air temperature is used only for qualitatively checking the trends indicated by the more complete test results obtained in the tests with the neoprene-coated grid assembly.

The jet thrust, which is calculated from the test measurements by the method described in reference 1, represents the gross thrust of only the exhaust jet and is therefore greater than the actual thrust that would be obtained in flight by an amount equal to the drag associated with the momentum of the air entering the engine. The jet thrust may be given by the expression

$$F_j = \frac{W}{g} V_j \qquad (1)$$

where

F_j jet thrust developed by engine, pounds

W combustion-air weight flow through engine, pounds per second

g acceleration of gravity, 32.2 feet per second per second

V_j effective jet velocity, feet per second

The performance comparison at the two values of combustion-air temperature includes comparisons of combustion-air weight flow, effective jet velocity. and gross jet thrust for the same conditions of fuel flow and simulated ram pressure.

RESULTS AND DISCUSSION

A summary of the test results obtained with the neoprene-coated grid assembly at variable conditions of fuel flow and simulated ram pressure for combustion-air temperatures of approximately 80° and 130° F is presented in table I. Reference 2 shows that no noticeable valve deterioration occurred during the total period of operation; hence, the test results give a true picture of the performance of the engine at the two values of combustion-air temperature for the range of ram pressures and fuel flows tested. The variations of combustion-air flow, effective jet velocity, and jet thrust with fuel flow are presented in figures 2, 3, and 4, respectively, for simulated ram pressures of 19, 38, and 58 inches of water and for combustion-air temperatures of approximately 80° and 130° F. Although the reproducibility of the test data is shown to be only of the same order of magnitude as the measured effects of the change in combustion-air temperature on the engine performance, a sufficient number of data points was obtained to permit determination of an average effect of change in combustion-air temperature on the engine performance.

It is evident from figures 2 to 4 that the increase in combustion-air temperature from 80° to 130° F has a detrimental effect on the engine performance. This loss of engine performance may be conveniently summarized as follows:

Simulated ram pressure (in. water)	Average reduction due to change of inlet combustion-air temperature from 80° to 130° F (percent)		
	Combustion-air flow	Effective jet velocity	Jet thrust
19	0	10	10
38	4	2	6
58	2	7	9

The reduction in jet thrust from 6 to 10 percent obtained with the increase of combustion-air temperature from approximately 80° to 130° F is roughly equivalent to the percentage increase in the absolute temperature of the combustion air. The loss of engine thrust due to the increase of combustion-air temperature is much greater than that accounted for by the reduction of combustion-air consumption; this result indicates that a loss of engine thermal efficiency is also involved, as reflected by a reduction in effective jet velocity.

A summary of the test data obtained with a standard grid assembly at simulated ram pressures of 40 and 58 inches of water for a combustion-air temperature of approximately 130° F is presented in table II. A total of about 20 minutes operating time was accumulated. In this interval no evidence of serious valve deterioration was noted. A comparison of these results with those of reference 1, which were established for a combustion-air temperature of 70° to 80° F, is made in figures 5 to 7. The performance results of reference 1 are represented by solid lines; dashed lines are faired through the limited data points obtained for a combustion-air temperature of 130° F. Trends similar to those obtained with the neoprene-coated grid assembly are shown for a change in combustion-air temperature.

A comparison of the frequency values given in table II with those obtained in the tests of reference 1 shows that the engine-cycle frequency is not affected by the change of combustion-air temperature.

SUMMARY OF RESULTS

The results of a sea-level thrust-stand investigation conducted on a 22-inch-diameter pulse-jet engine show that, when the combustion-air temperature is increased from 80° to 130° F for the same conditions of simulated ram pressure and fuel flow, the following losses in engine performance are obtained:

Nominal simulated ram pressure (in. water)	Fuel-flow range (lb/hr)	Average reduction due to change of inlet combustion-air temperature from 80° to 130° F (percent)		
		Combustion-air flow	Effective jet velocity	Jet thrust
19	2000-2400	0	10	10
38	2200-3000	4	2	6
58	2400-3400	2	7	9

The percentage reduction in jet thrust is approximately equivalent to the percentage increase in absolute temperature of the combustion air for the same conditions of fuel flow and simulated ram pressure over the range tested.

The reduction of engine thrust is due to decreases in both combustion-air consumption and engine thermal efficiency.
